

# Punctuation

Extended documentation for mathematical symbols & functions is [here](#).

symbol	meaning
@m	the at-symbol invokes <a href="#">macro</a> <code>m</code> ; followed by space-separated expressions or a function-call-like argument list
!	an exclamation mark is a prefix operator for logical negation ("not")
a!	function names that end with an exclamation mark modify one or more of their arguments by convention
#	the number sign (or hash or pound) character begins single line comments
#=	when followed by an equals sign, it begins a multi-line comment (these are nestable)
=#	end a multi-line comment by immediately preceding the number sign with an equals sign
\$	the dollar sign is used for <a href="#">string</a> and <a href="#">expression</a> interpolation
%	the percent symbol is the remainder operator
^	the caret is the exponentiation operator.
&	single ampersand is bitwise and
&&	double ampersands is short-circuiting boolean and
	single pipe character is bitwise or
	double pipe characters is short-circuiting boolean or
⊕	the unicode xor character is bitwise exclusive or
~	the tilde is an operator for bitwise not
'	a trailing apostrophe is the <a href="#">adjoint</a> (that is, the complex transpose) operator $A^H$

<code>*</code>	the asterisk is used for multiplication, including matrix multiplication and <a href="#">string concatenation</a>
<code>/</code>	forward slash divides the argument on its left by the one on its right
<code>\</code>	backslash operator divides the argument on its right by the one on its left, commonly used to solve matrix equations
<code>()</code>	parentheses with no arguments constructs an empty <a href="#">Tuple</a>
<code>(a, ...)</code>	parentheses with comma-separated arguments constructs a tuple containing its arguments
<code>(a=1, ...)</code>	parentheses with comma-separated assignments constructs a <a href="#">NamedTuple</a>
<code>(x;y)</code>	parentheses can also be used to group one or more semicolon separated expressions
<code>a[]</code>	<a href="#">array indexing</a> (calling <a href="#">getindex</a> or <a href="#">setindex!</a> )
<code>[,]</code>	<a href="#">vector literal constructor</a> (calling <a href="#">vect</a> )
<code>[:]</code>	<a href="#">vertical concatenation</a> (calling <a href="#">vcat</a> or <a href="#">hvcats</a> )
<code>[ ]</code>	with space-separated expressions, <a href="#">horizontal concatenation</a> (calling <a href="#">hcat</a> or <a href="#">hvcats</a> )
<code>T{ }</code>	curly braces following a type list that type's <a href="#">parameters</a>
<code>{ }</code>	curly braces can also be used to group multiple <a href="#">where</a> expressions in function declarations
<code>;</code>	semicolons separate statements, begin a list of keyword arguments in function declarations or calls, or are used to separate array literals for vertical concatenation
<code>,</code>	commas separate function arguments or tuple or array components
<code>?</code>	the question mark delimits the ternary conditional operator (used like: <code>conditional ? if_true : if_false</code> )
<code>" "</code>	the single double-quote character delimits <a href="#">String</a> literals
<code>""" """</code>	three double-quote characters delimits string literals that may contain <code>"</code> and ignore leading indentation
<code>' '</code>	the single-quote character delimits <a href="#">Char</a> (that is, character) literals

<code>`</code>	the backtick character delimits <a href="#">external process</a> ( <code>Cmd</code> ) literals
<code>A...</code>	triple periods are a postfix operator that "splat" their arguments' contents into many arguments of a function call or declare a varargs function that "slurps" up many arguments into a single tuple
<code>a.b</code>	single periods access named fields in objects/modules (calling <a href="#">getproperty</a> or <a href="#">setproperty!</a> )
<code>f.()</code>	periods may also prefix parentheses (like <code>f.()</code> ) or infix operators (like <code>.+</code> ) to perform the function element-wise (calling <a href="#">broadcast</a> )
<code>a:b</code>	colons ( <code>:</code> ) used as a binary infix operator construct a range from <code>a</code> to <code>b</code> (inclusive) with fixed step size <code>1</code>
<code>a:s:b</code>	colons ( <code>:</code> ) used as a ternary infix operator construct a range from <code>a</code> to <code>b</code> (inclusive) with step size <code>s</code>
<code>:</code>	when used by themselves, <a href="#">Colons</a> represent all indices within a dimension, frequently combined with <a href="#">indexing</a>
<code>::</code>	double-colons represent a type annotation or <a href="#">typeassert</a> , depending on context, frequently used when declaring function arguments
<code>:( )</code>	quoted expression
<code>:a</code>	<a href="#">Symbol</a> <code>a</code>
<code>&lt;:</code>	subtype operator
<code>&gt;:</code>	supertype operator (reverse of subtype operator)
<code>=</code>	single equals sign is <a href="#">assignment</a>
<code>==</code>	double equals sign is value equality comparison
<code>===</code>	triple equals sign is programmatically identical equality comparison.
